Implications of Monetary Policy for Corporate Sector and Economic Growth in Pakistan

Safia Shabbir

STATE BANK OF PAKISTAN

SBP Working Paper Series

Editor: Dr. Hamza Ali Malik

The objective of the SBP Working Paper Series is to stimulate and generate discussions, on different aspects of macroeconomic issues, among the staff members of the State Bank of Pakistan. Papers published in this series are subject to intense internal review process. The views expressed in the paper are those of the author(s) and do not necessarily reflect those of the State Bank of Pakistan.

Implications of Monetary Policy for Corporate Sector and Economic Growth in Pakistan

Safia Shabbir, Deputy Director, State Bank of Pakistan, safia.shabbir@sbp.org.pk

Abstract

Using micro data on non-financial listed companies in Pakistan, over the period of 2000-2010, this paper emphasizes the impact of monetary policy on economic growth through balance sheet channel. At first step, monetary tightening deteriorates the net worth of the firms and leads to cash flow squeeze which in turn affects the economic growth. We find this impact to last for three years over the balance sheets of the firms. Since industrial sector drives the economic growth, we forecast corporate profitability at the second step. Empirical investigation shows that corporate profitability reverts to its mean at the rate of 25 percent. During peak, mean reversion is 30 percent while it is 19 percent during trough implying that recession stays relatively longer and economic revival is slow during recessionary phase.

Non-Technical Summary

The impact of monetary policy primarily transmits to the industrial sector through balance sheet channel. Owing to the inverse relationship between interest rate and demand for loanable funds, the balance sheet channel states that monetary tightening affects the borrower's balance sheet and output through their net worth and cash flows. Rise in policy rate erodes the net worth of the firms which reduces the value of their collateral and lowers their credit worthiness. Also rise in interest rate increases the financial expenses of the firms, reduces the profitability of the corporate and leads to cash flow squeeze. Since most firms borrow to meet their working capital requirements; fall in short term borrowing reduces the cash flows, output, and profitability of the firms. This in turn hampers the economic growth.

In this paper, we investigate how long does it take to completely wipeout the impact of monetary policy from the balance sheets of the borrowers and found these impacts to last for at most 3 years. Moreover, focusing on the role of corporate profitability towards the economic growth we estimated and forecasted the level of corporate profitability and its mean reversion. We found that corporate profitability closely follows the GDP growth trend. However, speed of mean reversion is asymmetric during peaks and troughs. Corporate profitability reverts to long run growth path with a higher rate during peaks, while this reversion is much slower during recession. This implies that recession stays relatively longer and economic revival is slow during recessionary phase.

1. Introduction

In the wake of global economic crisis, the international economic arena has witnessed pronounced changes in the recent past. Many economies including South Asian region suffered twin deficits and stagnant economic growth along with growing inflationary pressures. Several of them, including Pakistan, used monetary policy as a stabilization tool, and raised interest rates to ensure stable macroeconomic environment. Since, the degree of effectiveness of monetary policy depends upon the size as well as sources of financing fiscal deficit; monetary contraction in the wake of growing fiscal imbalances and higher inflationary pressure reduced the supply of loanable funds and leads to crowding out of the private sector in Pakistan. This in turn reduced the output and dampened the economic growth.

State Bank of Pakistan (SBP) uses policy rate as a stabilization tool to achieve price stability, which can provide an environment conducive for businesses and stimulate economic growth. Since long term sustainable economic growth depends upon a flourishing industrial sector, this study aims at exploring the impact of monetary policy transmitted through the balance sheet of the non-financial corporate sector to economic growth and observes the behavior of corporate sector of Pakistan during a complete business cycle. This study is divided into two parts. In first part, following the theoretical groundings set by Bernanke and Gertler (1995), we compute the impact of monetary contraction over the balance sheets of the corporate sector. We find that monetary tightening affects the borrower's balance sheet through two sub channels, i.e. net worth channel and cash flow channel, in which the former affects the credit worthiness of the firms, while the later affects the cash flow and profits of the companies. By classifying firms as SME and large, Shabbir (2012) observed that monetary contraction affects the net worth and cash flow of both the SMEs and large firms, with SMEs getting more hit on their cash flows, short-term borrowing, and revenues. Adding to the existing literature, this study observes how net worth erosion and cash flow squeeze hampers the economic growth and estimates the length of these effects over the balance sheets of corporate sector. In second part, following the economic theory that suggests that under competition, the rate of return on investment tends towards equality and profitability is mean reverting within as well as across industries (Stigler, 1963; Fama and French, 2000, Fama and MacBeth 1973; Allen and Salim, 2002; Ahmed 2005), we investigate whether profitability is mean reverting in Pakistan and observe the behavior of non-financial corporate sector of Pakistan during a complete business cycle. Since, the sample under observation covers almost 76 percent of industrial GDP; we draw inferences for long run economic growth in Pakistan.

Road map of the later sections of this paper is as follows. Section 2 empirically investigates the monetary transmission mechanism under fiscal dominance and observes the impact of monetary tightening over economic growth. Section 3 links the balance sheet channel of monetary transmission with corporate profitability and the business

cycle fluctuations. Section 4 concludes the paper and provides policy recommendations for the researchers and policy makers.

2. Monetary Transmission, Fiscal Dominance and Economic Growth

Sustainable long term economic growth cannot be achieved without a growing industrial sector. The industrial sector of Pakistan holds almost 26 percent share in GDP and pulls the overall economy through backward and forward linkages in the agriculture & services sector and generates further employment opportunities. Like fertilizer and automobile sector supports and improves the productivity of agriculture sector (for example through higher productivity of tractors); growing textiles pulls the cotton and ginning industry and generates demand for inputs mainly from agriculture sector. Energy sector not only affects the productivity of corporate sector itself, but it also affects the productivity of other sectors including agriculture and services sector. Growth of cement sector is directly linked with the growth of real GDP, and is also reflexive of housing and infrastructure development in the country. Additionally, strong industrial sector promotes exports, which in turn improves the balance of payments position of the country. Given the importance of industrial sector, we explore how monetary policy affects the productivity and profitability of corporate sector.

Pakistan economy is currently facing higher fiscal dominance, which built inflationary pressures on the economy over time. Literature also suggests that in the presence of fiscal dominance, central bank cannot ensure price stability unless fiscal authority ensures the fiscal discipline (Zhou, 2012; Choudhri and Malik, 2012; Kumhof et.al 2010; Sidaoui 2003; Sargent and Wallace, 1981). Nevertheless, SBP increased policy rate during 2004-2010 to control inflationary pressure. Evidence on financial accelerator in Pakistan suggests, “*pass-through of policy decisions to borrowers is greater during monetary contractions*” (Choudhry et. al 2012); banks reallocated their funds and diverted credit towards large firms who are also capable of mobilizing credit through various resources, including the option of issuing commercial papers. Whereas small firms failed to tap resources from financial sector and get bigger hit (Shabbir, 2012). Detailed analysis shows that almost 70 of the credit demands by firms are only meant for financing their working capital. Portfolio adjustment by the banks thus reduces the production of companies and dampens the economic growth whereby increasing the financial cost on their existing debt liabilities.

2.1.1 Data and Research Methodology

To explore the balance sheet channel of monetary transmission, we study the behavior of 213 non-financial companies over 11 years (2000-2010). These companies are listed at Karachi Stock Exchange and broadly belong to textiles, cement, chemical, sugar, automobile, energy, and fertilizer sectors. These companies hold almost 76 percent share

in Industrial GDP. Micro information¹ on the audited financial accounts of these companies is collected through their annual reports. Due to limited availability of annual reports of listed companies, the analysis is constrained to 213 companies observed over 11 years. However, the length of this database is enough to cover a complete business cycle of Pakistan economy.

Information on capital employed, total dividend, current assets is collected from “Balance Sheet Statistics of Joint Stock Companies Listed at Karachi Stock Exchange” published by SBP. Data on number of shares, face value of shares, cash dividend, and stock dividend is collected from Karachi Stock Exchange. To collect information on break up of real and nominal GDP, and inflation, we used various editions of “Pakistan Economic Survey” annually published by Ministry of Finance, while data on overnight interest rate is collected from SBP.

We, therefore, compute the effects of monetary transmission on the balance sheets of the corporate sector through two sub channels; i) The Net worth channel ii) The Cash flow channel. We then observe how monetary transmission affects the economic growth.

2.1.2 The Net Worth Channel

Monetary contraction increases the interest rate, reduces the asset prices and directly affects the credit worthiness of borrowing firm by eroding the value of its collateral. Weak firms back the depleting value of their equity with surplus on revaluation of their assets, which provide them a cushion for a shorter time. However, if the financial health of the firm does not improve, businesses close their operations. Moreover, banks extend credit to the firms on the basis of their credit worthiness. During monetary contraction, net worth of the firms reduce sharply, and due to limited supply of loanable funds, banks redirect their funds from small firms to large firms assuming them less risky (Oliner and Rudebusch, 1996; Wesche, 2000; Guariglia and Mateut, 2006; Gertler and Gilchrist, 1994).

Following the definition of Bernanke and Gertler (1995), we define net worth as the difference between total assets and total liabilities of a firm and use linear panel data models of fixed effects and random effects to estimate the effect of monetary contraction over the net worth of a firm. The baseline model is defined as:

$$NW_{it} = \alpha + X_{it}\beta + u_i + \varepsilon_{it} \quad i = 1, 2, \dots, N \quad (1)$$

Where, NW is net worth to Asset ratio of *i*th firm observed over the period *t*, u_i is between-entity error, ε_{it} is within-entity error while, *X* is a set of independent variables:

¹ share holder’s equity, surplus on revaluation of assets, short term and long term debt liabilities of the companies, inventories, total assets, net sales, financial expenses, profit before tax, profits after tax, depreciation

$$X = f(\text{ONIR}, \text{FINS}, \text{SDA}, \text{LDA}, \text{DA}, \text{SDS}, \text{INVS}),$$

Where, ONIR is defined as overnight rate, FINS is the ratio of financial expenses of the firm to its assets, SDA is the ratio of short term debt of firm to its assets, LDA is the ratio of long term debt of the firm to its assets, DA is total debt of ith firm to its asset, SDS is ratio of short term debt of a company to its sales, INVS is the ratio of inventories to assets, while INVS is the inventories ith firm as a ratio of its output. Selection of these variables is made on the basis of economic theory and existing literature on monetary transmission through balance sheet channel. To capture the effect of individual heterogeneity across the sample firms, we use the same set of variables to estimate fixed effect model of linear panel data model as:

$$NW_{it} = \alpha_i + X_{it}\beta + u_i + \mathcal{E}_{it} \quad i = 1, 2, \dots, 213 \quad (2)$$

We use Hausman test to decide between using the fixed effect model and the random effect model. The value of Hausman is 0.85 (Prob > chi² = 0.85) which suggest using the random effect model. We, therefore, report the results obtained from random effect model in Table 1 in the Annexure. Additionally, robust standard errors are used to control for heteroskedasticity in the model. To see the length of effect of monetary policy on the net worth of the firm, we take lead of net worth to asset ratio. The model takes the following form:

$$NW_{it+k} = \alpha + X_{it}\beta + u_i + \mathcal{E}_{it} \quad k = 1, 2, 3, \dots, N \quad (3)$$

The results obtained are reported in Table 1.

2.1.3 The Cash Flow Channel

Cash flow channel measures the impact of monetary contraction on the liquidity position of the firm. Increase in interest rate raises the financial expenses of the firms and creates liquidity issues for the firms, thereby leading to cash flow squeeze. Literature suggests this impact can be observed on balance sheets of the firms at the end of the first quarter, since this study uses annual audited accounts of the firms, we successfully capture the impact of monetary contraction over the balance sheets of corporate sector of Pakistan (Wesche ,2000; Zaderey, 2003; Guariglia and Mateut, 2006; Karim and Zulkefly, 2010; Özlü and Yalçın, 2010).

Following Karim and Zulkefly (2010), cash flow variable is calculated as a sum of firm's net profit and depreciation and amortization. Depending upon the value of Hausman test, which turns out to be lower than 0.5, we use linear panel data model of fixed effects to estimate the cash flow channel. The linear panel regression takes the following form.

$$CF_{it} = \alpha_i + X_{it}\beta + u_i + \mathcal{E}_{it} \quad i = 1, 2, \dots, 213 \quad (4)$$

Where CF is ratio of cash flow of *i*th firm to its assets over time period *t*. X is the set of explanatory variables that include FINS, SDA, LDA and INVA, defined above. Though heteroskedasticity is hardly an issue for micro panel models with less than 20 years, but based on results of WALD test for group wise heteroskedasticity, we use robust standard errors in the model to control for heteroskedasticity. Moreover, to observe the length of monetary policy effect over the cash flow of the firm, we take the lead of CF_{*it*}. We find this impact to last for 3 years, i.e. from *t* to *t* + 2. Thus the baseline regression is defined as:

$$CF_{it+k} = \alpha_i + X_{it}\beta + u_i + \varepsilon_{it} \quad k = 1, 2, 3, \dots, N \quad (5)$$

Empirical results from these regressions are presented in Table 2 in Annexure.

2.1.4 Balance Sheet Channel and Economic Growth

To examine the impact of monetary transmission on economic growth, we introduce output buoyancy to the model, which is defined as a ratio of percentage change in firms output to the percentage change in industrial GDP. The assumption behind defining this variable is to observe how a company's output responds to the changes in total output of the economy. We then observe the behavior of output buoyancy in response to changes in cash flow and net worth of the firm along with other key variables. Empirical model of fixed effect² linear panel data model, therefore, takes the following form:

$$OB_{it} = \alpha_i + X_{it}\beta + u_i + \varepsilon_{it} \quad i= 1, 2, 3, \dots, 213 \quad (6)$$

OB is output buoyancy of *i*th firm over time *t*. while X = f (NW, CF, DA, INVA, ONIR, FINS). Based on the results from WALD test for group wise heteroskedasticity, we use robust standard errors to tackle the issue of heteroskedasticity. Further to estimate the length of current monetary policy over economic growth, we take lags of OB_{*it*} as done in the previous parts of this section. The results are presented in Table 3 in Annexure.

2.2 Empirical Findings

Empirical results obtained for net worth channel are reported in Table 1 in Annexure. These results are in line with the theoretical groundings of the balance sheet channel. Our estimates show that the impact of rise in ONIR on the net worth of a firm lies between 2- 9 percent, which affect the short term borrowing pattern of the firms and translates into an increase in the financial expenses of the firms. Additionally, banks use 3 month and 6 month KIBOR as bench mark for lending, and link their long term lending rate with KIBOR. In this scenario, any increase in policy rate immediately increases the financial expenses of the firms and also hit the long term liabilities of the companies. We observe this impact ranges between 4-12 percent. Since, a large

² The value of Hausman test turns out 0.11. Thus we use fixed effect linear panel data model.

part of the corporate borrowing is meant for working capital; SDA hits the net worth of the firm by 60 percent, while it is 37 percent for total debt liabilities (DA), implying high liquidity constraints of the corporate sector of Pakistan.

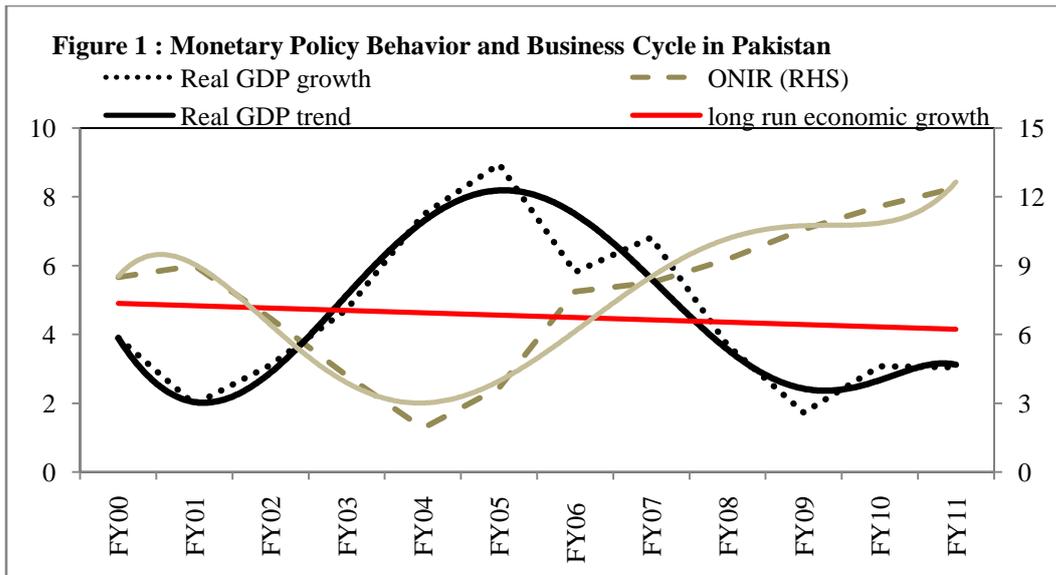

In the second step, we take lead of NW in first period, and find that monetary tightening in period one affects the DA in following year and this impact is at least 5 percent. These results are significant at 1 percent. Unlike the literature on balance sheet channel that states firms start inventory accumulation during the first quarter, we do not find any evidence of inventory accumulation by firms during the first year. However, we observe this trend in 2nd period.

Results from cash flow channel are reported in table 2. These results are also in line with the economic theory. We find that SDA affects the cash flow by 22 percent, while the impact of LDA is relatively low (3 percent). The wave of monetary tightening affects the cash flow of a firm for almost three years, however, the impact of SDA and LDA decelerates over time. These results are significant at 1 percent and 5 percent. We find evidence for inventory accumulation in 2nd and 3rd periods ($t + 1$ and $t + 2$), which supports the cash flow of the firm.

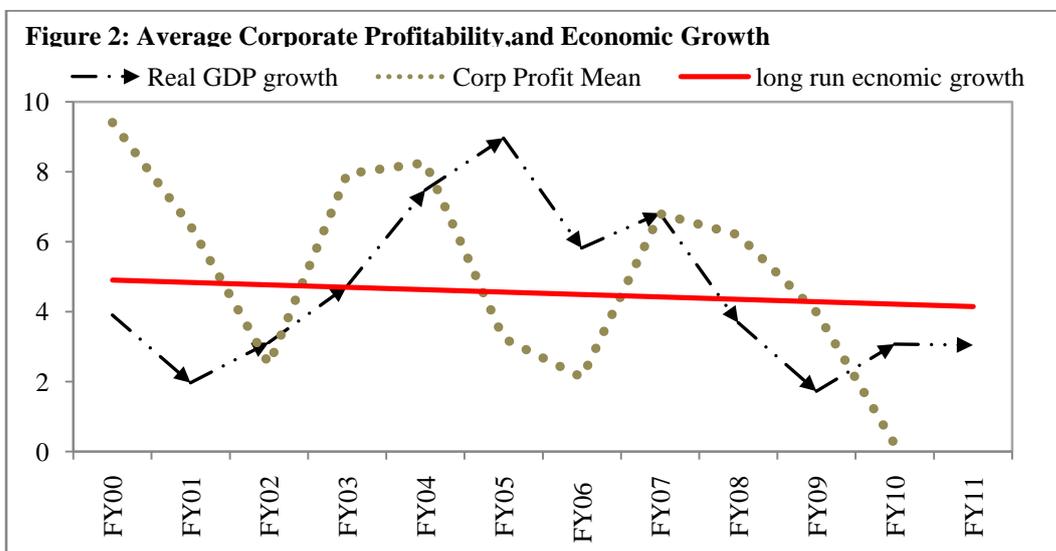

Table 3 provides empirical findings on relationship between NW, CF and other debt variables with output buoyancy (OB). The value of OB is greater than 1, which suggests that OB is highly influenced with the cash flow, and borrowing behavior of the firm. This supports the argument that liquidity is the key driving force behind a sound business. High cash flow keeps the firm solvent and helps running the business. We do not find any evidence that net worth of the firm matters for the long term growth of economy. Nonetheless the importance of net worth to have access to the loanable funds cannot be denied. Moreover, we find that impact of cash flow affects the economic growth for 3 years, though the degree falls in 2nd and 3rd years.

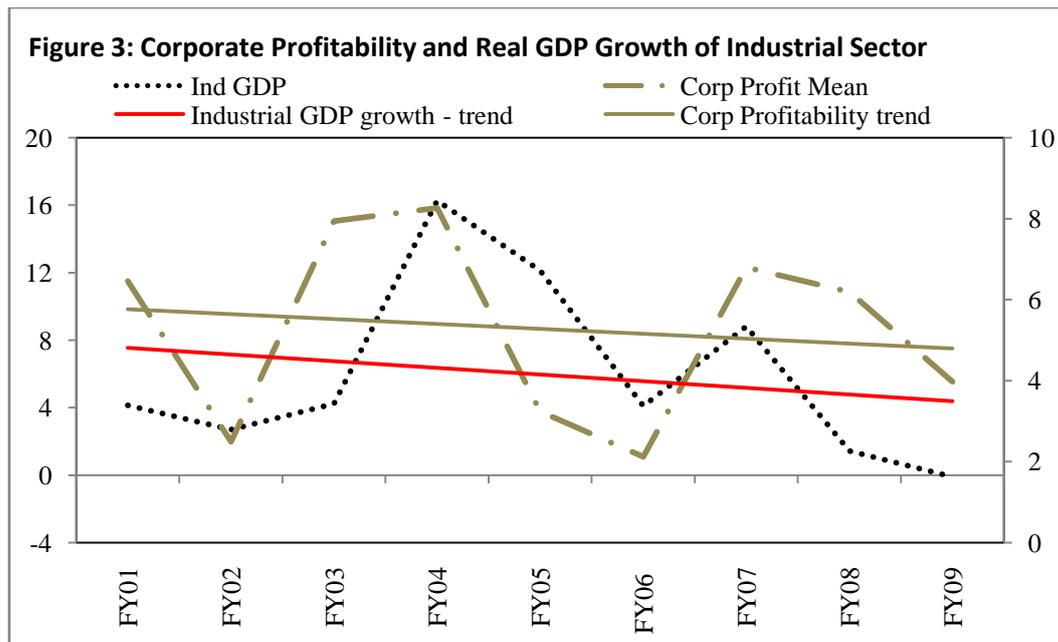

3 Monetary Transmission, Corporate Profitability and Business Cycle

Long run sustainable economic growth depends upon a flourishing corporate sector, which cannot be achieved unless stabilizing policies provide a macroeconomic environment conducive for businesses. Monetary contraction as observed in previous section, affects the cash flow of firms, and reduces their profit margins over time, which may alter the course of long run economic growth and push economy into prolonged recession. To investigate this hypothesis, we use the micro data on financial accounts of the non-financial sector, utilized in the earlier section. The length of this data is enough to observe the behavior of corporate sector in response to monetary policy over a complete business cycle (see Figure 1).

Literature on corporate profitability suggests that under competition, rate of return on investment across industries equalizes over time, implying that profitability of corporate sector reverts to its mean within as well as across industries. High competition within and across industry does not allow the firms to earn monopoly profits for a longer period of time and thus reduces the profit margin of firms over time and corporate profitability reverts to its mean value. Extending this phenomenon to economic growth, this theory implies that once the path for the long run economic growth is set, industrial sector will follow the same trend. Graphical analysis, done on the basis of empirical findings of the subsequent section shows that corporate profitability in Pakistan reverts to its mean, but Pakistan economy has a slightly downward trend for long term economic growth, which keeps the economy moving in the same spiral (see Figure 2 and Figure 3).

As shown in the earlier section, monetary policy stimulates economic growth through balance sheet channel, while corporate profitability drives the industrial GDP growth and thus the growth of economy as a whole. However, in order to assess the speed of mean reversion during peak and trough of business cycle, we use Fama and MacBeth (1973) methodology and find asymmetric behavior of mean reversion during peak and through which implies, monetary contraction during recession may lead to prolonged economic recession.

3.1 Research Methodology

Following the methodology of Fama and MacBeth (1973) we forecast the profitability of corporate sector of Pakistan and compute the mean reversion rate during peak and trough of business cycle. Instead of using a time series model which may not provide precise estimates due to shorter time series, we use year-by-year cross section regressions and use their average slopes and time series standard errors to draw inferences.

Step 1: Measuring the level of corporate profitability

To determine the expected profitability of the firm, we define the baseline cross section regression for each year. The model takes the following form:

$$Y_{it} / A_{it} = \alpha_i + X_{it} \beta_1 + u_i \quad i = 1, 2, 3, \dots, 213 \quad (7)$$

Y_{it} / A_{it} is profit before tax of i th firm as percent of its assets,

$$X_{it} = f(\text{DIVE}, \text{DD}, \text{TQ}, \text{LEV}, \text{CURR}, \text{CAPP}),$$

and u_i is error. We define DIVE as dividend to equity ratio, DD a dummy variable which is equal to 0 for dividend paying companies, and 1 for non-dividend payers, TQ is Tobin Q, which is calculated as the ratio of market capitalization of each firm to its assets, LEV is the leverage ratio defined as total liabilities of the firm to its shareholder's equity, CURR is the ratio of current assets of i th firm to its assets during time t , and CAPP is indicator of capital intensity computed as the ratio of capital employed of a company to its output. The results obtained from the regression are reported in Table 4 in Annexure.

Step 2: Linear Partial Adjustment Model for Forecasting Corporate Profitability in Pakistan

Based on the estimates obtained from cross section time series regression in equation 7, we estimate the following linear partial adjustment model to forecast corporate profitability:

$$CP_{it+1} = \beta_{0t} + \beta_{1t} DFE_{it} + \beta_{1t} CP_{it} + u_{it+1} \quad (8)$$

We define $CP_{it+1} = Y_{it+1}/A_{it+1} - Y_{it}/A_{it}$; $DFE_{it} = Y_{it}/A_{it} - E(Y_{it}/A_{it})$ and $CP_{it} = Y_{it}/A_{it} - Y_{it-1}/A_{it-1}$

CP_{it+1} is the corporate profitability in period 2, DFE_{it} is the deviation of corporate profitability from its mean value, $E(Y_{it}/A_{it})$, estimated from equation 7 and CP_{it} is the change in corporate profitability, while u_{it+1} is the error term. The estimates of this regression are presented in Table 5 in Annexure.

Following Ahmed (2005), we assume that all firms revert towards one equilibrium level of expected profitability and estimate the model as:

$$Y_{it+1}/A_{it+1} - Y_{it}/A_{it} = \beta_{0t} + \beta_{1t} (Y_{it}/A_{it}) + \beta_{2t} (Y_{it}/A_{it} - Y_{it-1}/A_{it-1}) + u_{it+1} \quad (9)$$

By estimating equation 9, we find the rate of reversion ($-\beta_1$) tends towards the long run equilibrium, which is the long run growth path of Pakistan economy. Results of this regression are reported in Table 6 in Annexure.

Since data under consideration covers a complete business cycle, we compute the speed of adjustment for the corporate sector in Pakistan to its mean value during Peak and Trough using equation 8 and 9. These findings are presented in Table 8 in Annexure.

Step 3: Non-Linear Partial Adjustment Model for Forecasting Corporate Profitability in Pakistan

Some studies on the mean reversion of the firms came across a non-linear behavior. For example Brook and Buckmaster (1976) observed that changes in earnings reverse from one year to another and speed of reversion towards mean is higher when the changes are strong. While estimating the speed of reversion towards mean for the listed companies in US, Fama and French (2000) also found evidence for the presence of non-linearities in the corporate profitability. We, therefore, also model the non-linearities using the Fama and French (2000) methodology. Our model takes the following form:

$$CP_{t+1} = \beta_{0t} + \beta_{1t} Y_{it}/A_{it} + \beta_{2t} E(Y_{it}/A_{it}) + \beta_{3t} NDFE_{it} + \beta_{4t} SPDFE_{it} + \beta_{5t} SNDFE_{it} + \beta_{6t} CP_{it} + \beta_{7t} NCP_{it} + \beta_{8t} SNCP_{it} + \beta_{9t} SPCP_{it} + u_{it} \quad (10)$$

In equation 10, $NDFE_{it}$ is defined as DFE_{it} , when DFE_{it} is negative; $SPDFE_{it}$ is the square of DFE_{it} when $SPDFE_{it}$ is positive; $SNDFE_{it}$ is the square of DFE_{it} when DFE_{it} is negative; NCP_{it} is CP_{it} when CP_{it} is negative; $SNCP_{it}$ is the square of CP_{it} when CP_{it} is negative; $SPCP_{it}$ is the square of CP_{it} , when CP_{it} is positive.

Results obtained from the equation are reported in Table 7 in Annexure. Value of $t(\text{Mean})$ is insignificant for the variables included to capture the non-linearities. Thus we do not find any evidence for the presence of non-linearities in our model.

3.2 Empirical Findings

Findings of the equation 7 are presented in Table 4. We regress Y_{it}/A_{it} over three different sets of sub-equations created by using the set of X defined in equation 7. Our results show that DIV, CURR, and CAPP increase the profitability of the firm. Since net worth of corporate sector of Pakistan is very weak, firms use surplus on revaluation of their assets to back their equity, high market capitalization in the wake of huge losses by the firms implies a weaker corporate sector. Thus aggregate profitability is pulled by the profitable firms, who are solvent, and making huge profits. Based on results obtained in table 4, we then forecast the level of corporate profitability. Estimates obtained by using 3 regression equations in Table 4 produce almost same results. We, therefore, rely on Model 3 in the later section.

Fama and French (2000) pointed out that variance of average slopes are very small, and thus standard errors of the average slopes should be inflated by 40 percent ($t(\text{Mean}) > 3.00$). Value of $t(\text{Mean})$ in our results are higher than 3.00, so our results are significant at 1 percent. Table 6 provides the estimates for mean reversion within industry as well across industry. These estimates are also in line with theory; Y_{it}/A_{it} holds the negative slope, while the slope of $E(Y_{it}/A_{it})$ is positive. Fama and French (2000) mentioned that “If there is little error in the prediction of $E(Y_{it}/A_{it})$, then the

two slopes should have equal absolute values". We find the mean reversion rate of the industry to be at 26 percent, while the speed of convergence towards the long run mean is 25 percent.

We observe the mean reversion rate during Peak and Trough of the business cycle. Results are reported in table 8. Our results show asymmetric behavior in the mean reversion rate during Peak and Trough. Findings show that during Peak, industry reverts to its mean at the rate of 31 percent, while this rate is 21 percent during recession, implying a slow recovery in recession. Focusing on the perspective of path for long term economic growth, we calculate the mean reversion rate during the whole cycle across all industries. Our estimates show that mean reversion gets even slower when the whole industrial sector is recession. Speed of reversion during Peak is 30 percent, while it is calculated as 19 percent during Trough. This result also imply that in the presence of an effective balance sheet channel, monetary policy can work as a stabilizing tool to achieve macroeconomic stability, and recession may stay longer if SBP increase the interest rate during recession. However, in the presence of fiscal dominance when seigniorage revenues directly add to the inflation, it is very challenging for SBP to stimulate the economy and maintain price stability.

4 Conclusion

In order to ensure stable macroeconomic environment and control inflationary pressure SBP increased interest rates during 2004-2010. This reduced the supply of loanable funds to the corporate sector and thus lowered their output, profitability and hampered economic growth.

Empirical findings of the paper shows that effects of monetary policy transmitted through the balance sheet channel to the corporate sectors, which deteriorated their net worth and led to cash flow squeeze. Our estimates shows that the impact of rise in ONIR over the net worth of a firm lies between 2- 9 percent, which affect the short term borrowing pattern of the firms and translates into an increase in the financial expenses of the firms. Additionally, since firms borrowing at a flexible interest rate are usually linked with benchmark interest rates (say KIBOR), any increase in policy rate immediately increases the financial expenses of the firms and also hit the long term liabilities of the companies. This impact is observed within the range of 4-12 percent.

Investigating the cash flow channel, we find that liquidity is the key driving force behind a sound business. ONIR translated through financial expenses hits the cash flow through SDA and LDA and lasts for almost three years. Additionally, we do not find evidence of inventory accumulation during the same period. In case of Pakistan, we observe inventory accumulation in 2nd and 3rd periods ($t + 1$ and $t + 2$), which supports the cash flow of the firm. Introducing output buoyancy of the firm, we investigate the impact of cash flow channel and net worth channel over economic

growth. Our results showed that monetary policy affects the economic growth through cash flow channel. These effects last for three years over the balance sheets of the firms.

Observing the behavior of 213 non-financial listed companies over a complete business cycle, this study also calculates the mean reversion rate for the corporate sector of Pakistan. We find that corporate profitability reverts to its long run mean with the speed of 25 percent. However, the speed is asymmetric during Peak and Trough. Corporate profitability reverts to its mean by 30 percent during peak, while this rate is 19 percent during Trough. This implies that once the path for the long run growth is set, corporate profitability will follow the trend. However, in case of Pakistan we experience a stagnant economic growth, with a slightly downward sloping curve. Though evidence is limited, but we can infer on the basis of micro data, that continuous downward movement of corporate profitability may change the steady state equilibrium of the economy.

Due to data limitations, scope of this study is limited to compute the effect of monetary contraction to the balance sheets of the corporate sector through credit channel, however, linkages from other channels including exchange rate channel may affect the input costs of the raw material during recession.
